Lightning Talks

Lightning Talks today:

Brett and Matt

Review of Previous Class

- Built an HTTP server
- Very basics of sockets
- Basics of HTTP protocol
- Got a server working (even proto-CGI!)

review of my http_serve8.py

More about Python implementation than OO design/strengths/weaknesses

One reason for this: Folks can't even agree on what OO "really" means

The Quarks of Object-Oriented Development - Deborah J. Armstrong:

http://agp.hx0.ru/oop/quarks.pdf

Is Python a "True" Object-Oriented Language?

(Doesn't support full encapsulation, doesn't require objects, etc...)

I don't Care!

Good software design is about code-reuse, clean separation of concerns, refactorability, testability, etc...

OO can help with all that, but:

- it doesn't guarantee it
- it can get in the way

Python is a Dynamic Language

That clashes with "pure" OO

Think in terms of what makes sense for you project – not any one paradigm of software design.

00 for this class:

"Objects can be thought of as wrapping their data within a set of functions designed to ensure that the data are used appropriately, and to assist in that use"

http://en.wikipedia.org/wiki/Object-oriented_programming

Even simpler:

Objects are data and the functions that act on them in one place.

In Python: just another namespace.

The OO buzzwords:

- data abstraction
- encapsulation
- messaging
- modularity
- polymorphism
- inheritance

You can do OO in C (see the GTK+ project)

"OO languages" give you some handy tools to make it easier (and safer).

- polymorphism (duck typing gives you this anyway)
- inheritance

OO is the dominant model for the past couple decades

You will need to use it:

- It's a good idea for a lot of problems
- You'll need to work with OO packages

Some definitions

```
class A category of objects: particular data and behavior:
A circle (same as a type in python)
```

```
instance A particular object of a class: a specific circle
```

```
object the general case of a instance – really any value (in Python anyway)
```

attribute something that belongs to an object (or class) – generally thought of as a variable, or single object, as apposed to a ...

method a function that belongs to a class

The class statement

```
class creates a new type object:
```

```
In [4]: class C(object):
    pass
    ...:
In [5]: type(C)
Out[5]: type
```

It is created when the statement is run - much like def

```
(note on "new style" classes)
```

Note about the book (TP):

Chapters 15 and 16 use a style that generally isn't recommended:

```
In [6]: class Point(object):
    ...:    pass
In [7]: p = Point()
In [8]: p.x = 4
In [9]: p.y = 2
```

Python is Dynamic – you can do this, but you generally want more structure, defaults, etc.

(it used to be a quick and dirty "struct" – but use a named tuple now)

About the simplest class:

```
>>> class Point:
\dots x = 1
   v = 2
>>> Point
<class __main__.Point at 0x2bf928>
>>> p
<__main__.Point instance at 0x2de918>
>>> Point.x
>>> p = Point()
>>> p.x
```

Basic Structure of a real class

```
class Point(object):
# everything defined in here is in the class namespace
    def __init__(self, x, y):
        self.x = x
        self.v = v
## create an instance of that class
p = Point(3,4)
## access the attributes
print "p.x is:", p.x
print "p.y is:", p.y
see: simple_class in code dir
```

The Initializer

The __init__ special method is called when a new instance of a class is created.

You can use it to do any set-up you need

```
class Point(object):
    def __init__(self, x, y):
        self.x = x
    self.y = y
```

It gets the arguments passed to the class constructor

self

The instance of the class is passed as the first parameter for every method.

"self" is only a convention – but you DO want to use it.

```
class Point(object):
    def a_function(self, x, y):
...
```

Does this look familiar from C-style procedural programming?

```
class Point(object):
    def __init__(self, x, y):
        self.x = x
    self.y = y
```

Anything assigned to a self. attribute is kept in the instance name space

That's where all the instance-specific data is.

```
class Point(object):
    size = 4
    color= "red"
    def __init__(self, x, y):
        self.x = x
        self.y = y
```

Anything assigned in the class scope is a class attribute – every instance of the class shares the same one.

```
class Point(object):
    size = 4
    color= "red"
...
    def get_color():
        return self.color
>>> p3.get_color()
    'red'
```

class attributes are accessed with self also..

Typical methods

```
class Circle(object):
    color = "red"
    def __init__(self, diameter):
        self.diameter = diameter

def grow(self, factor=2):
    self.diameter = self.diameter * factor
```

methods take some parameters, manipulate the attributes in self

```
Gotcha!
```

```
def grow(self, factor=2):
        self.diameter = self.diameter * factor
...

In [205]: C = Circle(5)
In [206]: C.grow(2,3)

TypeError: grow() takes at most 2 arguments (3 given)
```

Huh???? I only gave 2

LAB

We had such a good time last class – we'll do something similar

The goal is to build a set of classes that render an html page: sample_html.html

We'll start with a single class, then add some sub-classes to specialize the behavior

More details in week-06/LAB_instuctions.txt

LAB

Step 1:

- Create an "Element" class for rendering an html element (xml element).
- It should have class attributes for the tag name and the indentation
- the constructor signature should look like:
 Element(content=None) where content is a string
- It should have an "append" method that can add another string to the content
- It should have a render(file_out, ind = "") method that renders the tag and the strings in the content. file_out could be any file-like object. ind is a string with enough spaces to indent properly.

Lightning Talk

Lightning Talk:

Brett

Inheritance

In object-oriented programming (OOP), inheritance is a way to reuse code of existing objects, or to establish a subtype from an existing object.

. . .

objects are defined by classes, classes can inherit attributes and behavior from pre-existing classes called base classes, or super classes.

The resulting classes are known as derived classes or subclasses.

```
(http://en.wikipedia.org/wiki/Inheritance_
%28object-oriented_programming%29)
```

Subclassing

A subclass "inherits" all the attributes (methods, etc) of the parent class.

You can then change ("override") some or all of the attributes to change the behavior.

The simplest subclass in Python:

```
class A_Subclass(The_SuperClass):
    pass
```

A_subclass now has exactly the same behavior as The_SuperClass

Overriding attributes

Overriding is as simple as creating a new attribute with the same name:

```
class Circle(object):
    color = "red"
...
class NewCircle(Circle):
    color = "blue"
>>> nc = NewCircle
>>> print nc.color
blue
```

all the self instances will have the new attribute

Overriding methods

Same thing, but with methods

```
class Circle(object):
. . .
    def grow(self, factor=2):
        """grows the circle's diameter by factor"""
        self.diameter = self.diameter * factor
class NewCircle(Circle):
. . .
    def grow(self, factor=2):
        """grows the area by factor..."""
        self.diameter = self.diameter * math.sqrt(2)
```

all the instances will have the new method

"Here's a program design suggestion: whenever you override a method, the interface of the new method should be the same as the old. It should take the same parameters, return the same type, and obey the same preconditions and postconditions. If you obey this rule, you will find that any function designed to work with an instance of a superclass. like a Deck, will also work with instances of subclasses like a Hand or PokerHand. If you violate this rule, your code will collapse like (sorry) a house of cards"

ThinkPython 18.10

LAB

Step 2:

- Create a couple subclasses of Element, for a <body> tag and
 tag. Simply override the tag class attribute.
- Extend the Element.render() method so that it can render other elements inside the tag in addition to strings. Simple recursion should do it. i.e. it can call the render() method of the elements it contains.
- Deal with the content items that could be either simple strings or Elements with render methods...there are a few ways to handle that...

LAB

Step 3:

- Create a <head> element simple subclass.
- Create a OneLineTag subclass of Element: It should override the render method, to render everything on one line – for the simple tags, like:
 - <title> PythonClass Class 6 example </title>
- Create a Title subclass of OneLineTag class for the title.
- You should now be able to render an html doc with a head element, with a title element in that, and a body element with some <P> elements and some text.

Lightning Talk

Lightning Talk:

Matt

Overriding __init__

```
init common method to override
You often need to call the super class __init__ as well
class Circle(object):
    color = "red"
    def __init__(self, diameter):
        self.diameter = diameter
. . .
class CircleR(Circle):
    def __init__(self. radius):
        diameter = radius*2
        Circle.__init__(self, diameter)
exception to: "don't change the method signature" rule.
```

Overriding other methods

You can also call the superclasses other methods:

```
class Circle(object):
...
    def get_area(self, diameter):
        return math.pi * diameter / 2.0

class CircleR2(Circle):
...
    def get_area(self):
        return Circle.get_area(self, self.radius*2)
```

There is nothing special about __init__ except that it gets called automatically.

When to Subclass

"Is a" relationship: Subclass/inheritance

"Has a" relationship: Composition

When to Subclass

"Is a" vs "Has a"

You may have a class that needs to accumulate an arbitrary number of objects.

A list can do that – do should you subclass list?

Ask yourself:

- IS you class a list (with some extra functionality)? or
- Does you class HAVE a list?

You only want to subclass list if your class could be used anywhere is list is.

Attribute resolution order

When you access an attribute:

An_Instance.something

Python looks for it in this order:

- Is it an instance attribute?
- Is it a class attribute ?
- Is it a superclass attribute?
- Is it a super-superclass attribute?
- **5** ...

It can get more complicated...

http://www.python.org/getit/releases/2.3/mro/

What are Python classes, really?

Putting aside the OO theory...

Python classes are:

- Namespaces
 - One for the class object
 - One for each instance
- Attribute resolution order
- Auto tacking-on of self

That's about it - really!

Type-Based dispatch

From Think Python:

```
if isinstance(other, A_Class):
    Do_something_with_other
else:
    Do_something_else
```

Usually better to use "duck typing" (polymorphism) But when it's called for:

- isinstance()
- issubclass()

```
GvR: "Five Minute Multi- methods in Python": http://www.artima.com/weblogs/viewpost.jsp?thread=101605
```

We're going to the rest: steps 4 - 8 Step 4:

 Extend the Element class to accept a set of attributes as keywords to the constructor, i.e.:

```
Element("some text content",
    id="TheList",
    style="line-height:200\%")
```

```
( remember **kwargs ? )
```

 The render method will need to be extended to render the attributes properly.

You can now render some tags (and others) with attributes

Step 5:

 Create a "SelfClosingTag" subclass of Element, to render tags like:

```
<meta charset="UTF-8" />
```

- You will need to override the render method to render just the one tag and attributes.
- create a couple subclasses of SelfClosingTag for <meta> and
 (horizontal rule) and
 /> or ??? if you like

You can now render an html page with a proper <head> (<meta /> and <title> elements)

Step 6:

- Create an A class for an anchor (link) element. Its constructor should look like: A(self, link, content) - where link is the link, and content is what you see. It can be called like so: A("http://google.com", "link")
- You should be able to subclass from Element, and only override the __init__
 - Calling the Element __init__ from the A __init__

You can now add a link to your web page.

Step 7:

- Create U1 class for an unordered list (really simple subclass of Element)
- Create Li class for an element in a list (also really simple)
- add a list to your web page.
- Create a Header class this one should take an integer argument for the header level. i.e <h1>, <h2>, <h3>, called like:
- H(2, "The text of the header") for an <h2> header
- It can subclass from OneLineTag overriding the __init__,
 then calling the superclass __init__

Step 8:

- Update the Html element class to render the "<!DOCTYPE html>" tag at the head of the page, before the html element.
- You can do this by subclassing Element, overriding render(), but then calling the Element render() from the new render().

You now have a pretty full-featured html renderer – play with it, add some new tags, etc....Maybe integrate it into your http server...

multiple inheritance

Multiple inheritance: Pulling from more than one class

```
class Combined(Super1, Super2, Super3):
    def __init__(self, something, something else):
        Super1.__init__(self, .....)
        Super2.__init__(self, .....)
        Super3.__init__(self, .....)

(calls to the super class __init__ are optional - usage dependent)
```

Attribute resolution – right to left

Why would you want to do this?

mix-ins

Hierarchies are not always simple

- Animal
 - Mammal
 - GiveBirth()
 - Bird
 - LayEggs()

Where do you put a Platapus or an Armadillo?

Real World Example: FloatCanvas
